Accessibility Statement

This tutorial has been produced with accessibility in mind:

- All charts use a colourblind-friendly palette (seaborn 'colorblind' theme, avoiding red/green contrast).
- All figures include descriptive alt-text captions below them.
- Font sizes are set to 11pt minimum throughout for readability.
- Document uses semantic headings (H1, H2) to support screen reader navigation.

1. Introduction: Beyond Simple Predictions

In machine learning, Random Forests and other ensemble methods are highly commended for their prediction accuracy. By building a "forest" of uncorrelated decision trees, this method efficiently handles non-linear data and prevents overfitting. But in practical business applications, such as predicting whether a customer would discontinue their service (churn), knowing who will do so is only half the battle. To take preventative action, businesses must understand the reasons behind client attrition.

Standard neural networks and complex ensembles are often referred to as "black boxes" since it is difficult to understand how they make decisions. This course focuses on a single technique to open that box: Feature Importance (more precisely, Mean Decrease in Impurity, or MDI). By the time this lesson is over, you will understand how to utilize Python to extract a Random Forest model's underlying logic and turn those mathematical findings into practical business intelligence.

2. The Mechanics of Feature Importance

To understand how a Random Forest ranks features, we must examine the construction of each decision tree. When a tree divides its data at a node, it searches for the characteristic that best distinguishes the classes (e.g., Churn vs. No Churn).

The technique uses a statistic known as Gini Impurity to assess the quality of this split. The node is completely "pure" when the Gini impurity is 0, meaning that every customer in that branch is a member of the same class.

The overall reduction in Gini impurity that a certain feature contributes to the model, averaged over all of the forest's trees, is measured by the Mean Decrease in Impurity (MDI). If a feature like Contract Type consistently generates incredibly pure splits across hundreds of trees, it has a very high significance score. It is the mathematical equivalent of the statement, "This is the most useful piece of information I have for making my decision."

3. The Dataset and Preprocessing

The Telco Customer Churn dataset is used in this tutorial. For a telecom company, it contains a mix of account information, service specifics, and demographic data.

Before the model is trained, the data must be cleaned. The TotalCharges column in this dataset has concealed blank spaces that cause the data to appear as text rather than numbers. The few blank rows must be removed, and these must be converted to numerical values. Categorical text features, such

contract kind or internet service type, are converted into binary number columns that the Random Forest can handle using one-hot encoding (pd.get_dummies).

4. Training the Model

100 trees are used to train a Random Forest Classifier (n_estimators=100). Max_depth is crucially set to 10. Even though deeper trees increase raw training accuracy, they run the danger of overfitting, which is the memorization of noise rather than broad patterns. The model is compelled to depend on the strongest, most reliable features when depth is limited, which significantly boosts the accuracy of the ensuing Feature Importance analysis.

5. Visualizing the "Why"

Once the model is trained, the feature_importances_ attribute provided by scikit-learn can be extracted and visualised.

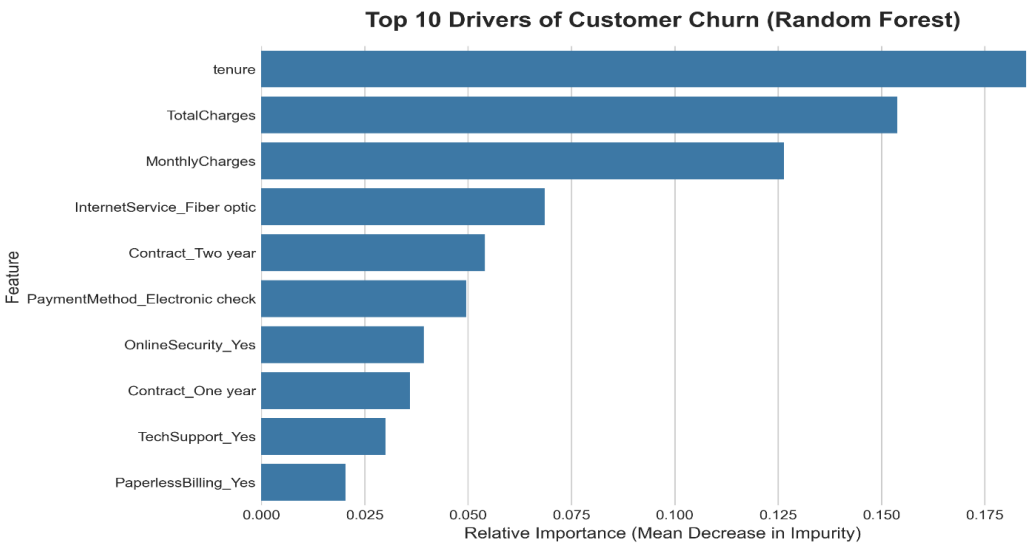

Figure 1: Relative importance of features based on Mean Decrease in Impurity. Alt-text: Horizontal bar chart showing top 10 churn drivers; tenure and month-to-month contract type are the two dominant features by a significant margin.

Looking at Figure 1, the model clearly identifies two dominant drivers of customer churn:

- Tenure: How many months the customer has been with the company.
- Contract_Month-to-month: Whether the customer is on a rolling monthly contract.

6. Translating Machine Learning to Business Reality

Proving the logic of the model is the final stage. While Tenure and Contract type play a major role in the Random Forest, visualising the raw data helps determine the direction of that relationship.

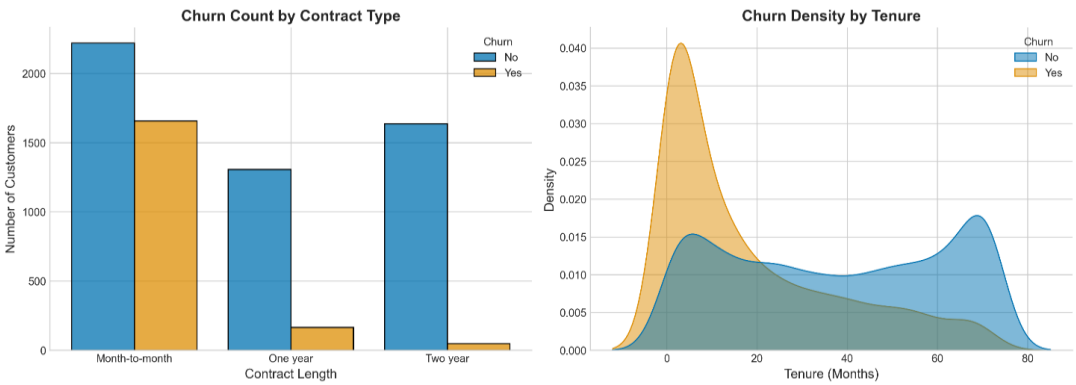

Figure 2: Real-world distributions of the top churn drivers. Alt-text: Left panel — grouped bar chart showing month-to-month customers churn far more than those on longer contracts. Right panel — density plot showing churn is concentrated in the first 1–5 months of tenure.

By plotting the specific features the model flagged as important, the business reality becomes clear:

- The Contract Effect: Customers on month-to-month contracts churn at a far greater rate than those on one-year or two-year contracts.
- The Tenure Effect: A significant spike in churn occurs during the first one to five months of service. A customer's likelihood of churning drops dramatically after their first year.

Business Value: Instead of just creating a list of "clients at risk," Feature Importance has identified a structural problem with the company. The first six months of a month-to-month contract should be the main emphasis of the company's onboarding and retention strategy.

7. Limitations of MDI

Even though Mean Decrease in Impurity is powerful, it is important to recognise its limitations:

- High-Cardinality Bias: MDI tends to assign higher importance to continuous or high-cardinality features (such as TotalCharges or Tenure) compared to low-cardinality binary features. This occurs because high-cardinality features offer more possible split points, creating more opportunities to reduce impurity regardless of true predictive value.
- Training-Set Only: MDI is computed on training data splits, not on unseen test data. This means it can reflect how well a feature memorises training patterns rather than how well it truly generalises.
- Alternative — Permutation Importance: A more robust alternative is Permutation Importance, which evaluates feature significance by randomly shuffling each feature on held-out test data and measuring the resulting drop in model performance. In scikit-learn, this is available via sklearn.inspection.permutation_importance(). It is less biased toward high-cardinality features and evaluates true generalisation.

For this tutorial's purposes, MDI provides a fast, practical, and interpretable starting point. For high-stakes decisions, combining MDI with Permutation Importance is best practice.

8. Conclusion

Black boxes are not necessary for Random Forests. We may close the gap between difficult machine learning mathematics and intelligible, useful insights by extracting and visualizing Feature Importance. By using this technique, a predictive model becomes an effective diagnostic tool that can directly influence corporate strategy.
